CORRELATION OF CHARACTERS IN EAR CORN

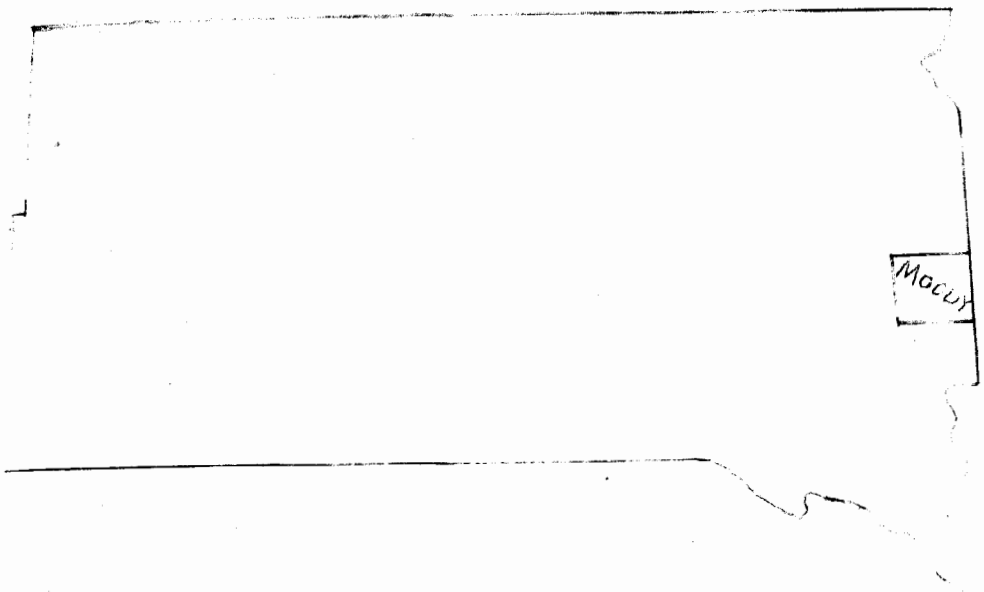
The idea has been prevalent that the most cylindrical ears of corn have the largest percentage of corn on them, and it has been the purpose of this study to determine the correlation coefficient between the degree of taper and the percentage of shelled corn on ears of Moody County White Dent.

History of Moody County White Dent

The history of Moody County White Dent was gotten mainly thru correspondence and personal interviews. The writer secured the corn with which he worked from Professor J. W. Wilson, Director of the South Dakota Experiment Station. This particular corn had been raised at Buckingham, Iowa, in the year 1915 from seed raised in South Dakota in 1914 and was to be used by Professor Wilson in feeding experiments.

Professor Wilson received his seed corn of this variety from Mr. J. A. Silvander of Elkton, (Moody County), South Dakota, three years ago. Mr. Silvander states in answer to an inquiry that he had raised this variety for five years and that he had gotten his original seed from Mr. Chas. Blandeneer of Elkton, South Dakota. Mr. Blandeneer in reply to the writer's letter states that he has raised Moody County White Dent for 18 years and that he had gotten his original seed from one of his neighbors. Mr. Blandeneer also states in his letter that at the time he got his first seed it was known as "King or something like that."

From the facts that this Moody County White Dent resembles Silver King very much and Mr. Blandeneer's statement that when he first got his seed it was known as "King or something like that," the writer is led to believe that the corn with which he worked was Silver King.



Outline map of South Dakota showing the location of Moody County, where Moody County White Dent has been grown for over 18 years.

Description

The corn with which the writer worked was white, quite smoothly dented and had a shelling percentage of 83. The kernels were of medium depth on a white cob.

Meaning of correlation

By correlation in plants or animals is meant the interrelation between separate characters by which they tend, in some degree at least, to move together. This relation is expressed in the form of a ratio, thus if an increase of one character is always followed by a corresponding and proportional increase in a related character, the correlation is said to be perfect and the ratio is 1. On the other hand if an increase in one character is followed by a corresponding and proportional decrease in a related character, the correlation is said to be negative and the ratio is -1, or perfect negative correlation. Again, if the characters in question are absolutely indifferent the one to the other, the correlation is said to be zero, indicating mere association without causative relation of any kind.

In corn as well as in any other living organism there is not necessarily a direct correlation between two characters, or a correlation coefficient of +1, or an absolute lack of correlation -1, or indifference 0, but the correlation coefficient may be between 0 and +1 or 0 and -1. Therefore we see that instead of being able to state that there is a direct positive or negative correlation between two characters, we can in most cases, only state to what degree the two characters are correlated.

If, for instance, we find a positive correlation coefficient of .12 when we compare the length and weight of ear corn, this would indicate that there was only 12 per cent of a perfect correlation between these two characters and that the correlation is of so small a degree, that we could not state that when the longest ears were selected they were also the heaviest.

Value of correlation studies

Correlation studies are valuable in that by this means one can ascertain the true relationship existing between different characters and thus have a definite guide in ones selection. They are of special value in that correlations are found between readily observable characters, such as taper of ears of corn, and characters which are not readily observable, such as the shelling percentage. So that if there was a perfect positive correlation between cylindrical ears and high shelling percentage all we would have to look for would be the cylindrical ear and be assured of a high shelling percentage.

Previous work on the correlation of different characters of ear corn

Considerable corn correlation work has been done but the writer wishes to confine his review to the correlations between different characters of ear corn.

Quantitative relationships have been determined by Davenport (3) in Leaming corn where he found a correlation of 0.87 ± 0.005 between weight and length in ear corn. He also found a correlation of 0.49 ± 0.02 between circumference and length of ear in inches.

Rietz and Smith (13) determined quantitative relationships between the following characters in Leaming ear corn:

1. Length and weight.
2. Circumference and weight.
3. Circumference and rows of kernels.
4. Length and circumference.
5. Weight and rows of kernels.
6. Length and rows of kernels.

They draw the following general conclusions, the correlations for length-weight and circumference-weight are high. The correlations for circumference-rows of kernels and length-circumference are fairly high. The correlation of weight-rows of kernels is low, while that of length-rows of kernels is probably insignificant.

The writer finds the following information with regard to correlation of different characters of ear corn in which the numerical coefficient has not been determined.

From his work with the Longfellow variety of corn Brigham (1) concludes that weight of corn is accompanied by an increase in the number of kernels, length of ears and weight of cob and also an increase in the weight of individual kernels.

From his data on Szekler Maize Fruwirth (6) concludes that with greater length of ear was correlated greater total weight of grain and greater weight of individual kernels, but also smaller thickness. Greater thickness of ear was correlated with smaller

percentage of grain and cob.

Thiel (9) found that the diameter of ear was correlated inversely with percentage of cob.

De Vries (10) found that breeding for a greater number of rows produced smaller kernels.

Hopkins, Smith and East (7) in studying physical and chemical characters in corn, conclude that high nitrogen content is correlated with a large proportion of corneous endosperm and high oil content with proportionately large embryo.

In determining the proportion of weight of grain to weight of cob Esterhaty (4) found no relationship between percentage of cob and other important characters.

Craig (2) found that there was a correlation between the relative amount of corneous endosperm present and the nitrogen content, similar to that of Hopkins, Smith and East.

Among other conclusions drawn by Mr. Craig were that ears producing grains which were medium to long in length and grains that were bright were the highest in nitrogen content and that cylindrical ears, smooth ears and selected ears of medium weight had the highest nitrogen content in the grain. He also found that heavy weight of grain and nitrogen content were correlated, as well as increase in the amount of ash and crude fibre together with the nitrogen content.

Hume, Champlin and Loomis (8) also report that high nitrogen content was correlated with a large proportion of corneous endosperm and high oil with a large embryo.

Little relation was found by Willard, Clothier and Weber (11) between specific gravity of kernels and nitrogen content.

The following recent experiments by Williams and Welton (12) are also of interest in this connection. They found that among

ears varying 2.44 inches in length the long ears led in yield by an average of 1.39 bushels per acre and conclude that such a difference is no greater than might have been expected had the seed used been identical.

From a nine year test they concluded that tapering ears have excelled cylindrical ears in yield by 1.65 bushels per acre. (This is of interest at this time since it tends to disprove the prevalent idea that the more cylindrical ears yield more, and from the writer's data given later the correlation between degree of taper of ears and shelling percentage is very small)

Williams and Welton also state that eight years of continuous selection of bare as compared with filled tips show an average difference of 0.34 bushels per acre in favor of filled tips.

Method of procedure

One thousand ears were taken from a pile of Moody County White Dent, no attempt being made at selection except to get ears that did not have any kernels knocked off from them. The diameter of the butt and tip ends of each ear were measured in millimeters, the measurements being taken 1 1/2 inches from the butt and tip ends.

The ears (corn and cob) were weighed and the weight recorded in grams with the exception of the first 258 ears which were recorded in ounces. The ears were then shelled and the weight of the cob alone was recorded.

Calculations

The degree of taper was gotten by dividing the diameter of the butt of the ear in millimeters by the diameter of the tip in millimeters. In other words if the diameter of the butt and tip were the same, the degree of taper would be represented by 1. If, however, the diameter of the tip was smaller than that of the

butt, the degree of taper would be greater than one. (Example, Butt 48 m. m. ÷ tip 40 m. m. = 1.2 degree of taper)

The percentage of shelled corn was gotten by subtracting the weight of the cob alone from the weight of the corn and cob and dividing this difference by the weight of the corn and cob.

The explanation of the method of finding the coefficient of correlation is rather long and if anybody wishes to study it in detail, it can be found in E. Davenport's book entitled "Principles of Breeding."

$Er = \pm \frac{0.6745\left[1-(.0889)^2\right]}{\sqrt{1000}} = \pm .0211$ (probable error.)

Conclusion

From the data the writer finds a positive correlation coefficient of 0.08991 $\pm$ 0.0211 between degree of taper of ears and shelling percentage, or that there is only about 9% of a perfect correlation, and therefore the writer concludes that the correlation is of too small a degree to warrant the statement that there is a correlation between degree of taper and shelling percentage in ears of Moody County White Dent corn.

Even if no correlation exists between the characters in question, we may still select the most cylindrical ears with the idea in mind that we are getting more uniform kernels and thus get a more uniform rate of seeding and consequently a more uniform stand of corn. But as far as the writer has been able to determine, there is no definite information on this subject and we do not know whether our supposition is correct or not.

The writer wishes to acknowledge valuable assistance from Dr. A. N. Hume and also from Mr. E. C. Ewing's bulletin (5).

Weight of ear and shelling percentage

Using the data previously quoted the writer, in this case, determined the coefficient of correlation between the percentage of corn on the ear and the weight of the ear.

1000	83202			8860.00	17994.70

$83202 \div 1000 = 83.202 \pm .063 M_s$ (Mean shelling percentage)

$886000 \div 1000 = 8.86\ \sigma_s^2$

$\sqrt{8.66} = 2.942 \pm .031\ \sigma_s$ (Standard Deviation)

$$r = \frac{17994.70}{1000(35.79)(2.942)} = .1707 \text{ (Coefficient of correlation)}$$

$$Er = \pm \frac{0.6745\ [1-(.1707)^2]}{\sqrt{1000}} = \pm .0206$$

Conclusion

A positive correlation coefficient of .1707 $\pm$ .0206 was found between weight of ear and shelling percentage, which leads the writer to believe that when heavy ears of Moody County White Dent corn are selected they have a larger percentage of corn on them than do the lighter ears.

Comparative germination percentage of corn stored on the cob and shelled corn

The writer was unable to find any data regarding the compa -ative germination percentage of corn stored on the cob and shell corn.

Ernest B. Brown, Acting in Charge of Corn Investigations, of the Bureau of Plant Industry, Washington, D. C., states in a letter to the writer with reference to the two methods of storing corn that, "We know of no experimental work that has been done bearing directly upon these two methods of storing. In our experimental work, we have frequently had corn stored both on the cob and as shelled corn; but in every case the corn has been selected early from the field, dried out thoroughly and stored under the best conditions available, and we have found that under such conditions the corn taken directly from the cob and the corn that had been previously shelled did not differ materially in germination percentage."

The writer used some of the Moody County White Dent corn in this test that was used for the problems previous worked out. This corn was brot to the Farm Crops store room in the Administration Building of the South Dakota State College on November 27, 1915, and was kept there at a temperature of 68 to 70 degrees Fahrenheit, until December 11, 1915 when some of the ears were shelled. Some shelled corn was placed in one sack and 25 ears were placed in another sack and both were hung up in the old Farm Crops laboratory where the temperature varied from freezing to as high as 90 degrees Fahrenheit, the average temperature probably being about 60 degrees.

These samples were left there until May 11, 1916 and 1000

kernel samples were taken from the shelled and unshelled and tested by the Rag Doll method.

The corn that was stored on the cob gave an average germination of 98 per cent while the shelled corn gave a germination of 96 per cent, showing a 2 per cent greater germination for the corn stored as ear corn.

The writer is led to believe that the difference in favor storing corn as ear corn would probably be greater than these tests indicate, if larger quantities are stored and if the corn is not allowed as good a two weeks of curing as these samples did while in the Farm Crops store room at the Administration Building.
