**Abstract:** Planting and harvesting times drive cropland phenology. There are few datasets that derive explicit phenological metrics, and these datasets use the visible to near infrared (VNIR) spectrum. Many different methods have been used to derive phenometrics such as Start of Season (SOS) and End of Season (EOS), leading to differing results. This discrepancy is partly due to spatial and temporal compositing of the VNIR satellite data to minimize data gaps resulting from cloud cover, atmospheric aerosols, and solar illumination constraints. Phenometrics derived from the downward Convex Quadratic model (CxQ) include Peak Height (PH) and Thermal Time to Peak (TTP), which are more consistent than SOS and EOS because they are minimally affected by snow and frost and other non-vegetation related issues. Here, we have determined PH using the vegetation optical depth (VOD) in three microwave frequencies (6.925, 10.65 and 18.7 GHz) and accumulated growing degree-days derived from AMSR-E (Advanced Microwave Scanning Radiometer on EOS) data at a spatial resolution of 25 km. We focus on 50 AMSR-E cropland pixels in the major grain production areas of Northern Eurasia (Ukraine, southwestern Russia, and northern Kazakhstan) for 2003–2010. We compared the land surface phenologies of AMSR-E VOD and MODIS NDVI data. VOD time series tracked cropland seasonal dynamics similar to that recorded by the NDVI. The coefficients of determination for the CxQ model fit of the NDVI data were high for all sites (0.78  $lt$  R<sup>2</sup>  $lt$  0.99). The 10.65 GHz VOD (VOD<sub>1065GHz</sub>) achieved the best linear regression fit ( $R^2$  = 0.84) with lowest standard error (SEE = 0.128); it is therefore recommended for microwave VOD studies of cropland land surface phenology. Based on an Analysis of Covariance (ANCOVA) analysis, the slopes from the linear regression fit were not significantly different by microwave frequency, whereas the intercepts were significantly different, given the different magnitudes of the VODs. PHs for NDVI and VOD were highly correlated. Despite their strong correspondence, there was generally a lag of AMSR-E PH VOD<sub>10.65GHz</sub> by about two weeks compared to MODIS peak greenness. To evaluate the utility of the PH determination based on maximum value, we correlated the CxQ derived and maximum value determined PHs of NDVI and found that they were highly correlated with  $R^2$  of 0.87, but with a one-week bias. Considering the one-week bias between the two methods, we find that PH of  $VOD<sub>10.65GHz</sub>$  lags PH of NDVI by three weeks. We conclude, therefore, that maximum-value based PH of VOD can be a complementary phenometric for the CxQ model derived PH NDVI, especially in cloud and aerosol obscured regions of the world.

### **1. Introduction**

Planting and harvesting times drive the phenologies of crops. Complex networks of factors influence when farmers plant particular crops and when they harvest them, including: recent and forecast weather; commodity prices, situation of local markets, and foreign crop conditions; crop insurance and governmental policies and subsidies; agronomic practices; and the cold hardiness, drought tolerance, or differential maturities of planted crop varieties. Most of these factors cannot be observed directly through remote sensing technologies. However, the remote sensing of land surface phenology (LSP) can reliably reveal the seasonality of vegetation in croplands in an ordinal sequence of broad phases: green-up onset (start-of-season, SOS), maturity onset, senescence onset, and dormancy onset (end-of-season, EOS). The dates or days of the year of the SOS and EOS are commonly used as phenological metrics (or phenometrics) to study the land surface phenology of croplands in relation to climatic and hydrological variability and, to some extent, the variation in land management [\[1\]](#page-18-0).

Cropland phenology is not equivalent to crop phenology. The phenologies of crops describe particular observable life history events in the specific crop species. Implicit in crop phenology is a human observing the crop at sufficiently close distance to distinguish the plant parts relevant to the phenological phases (or phenophases). In contrast, cropland phenologies describe the land surface phenologies of croplands captured through remote sensing. These may include a mixture of multiple crop types with non-crop elements such as roads, vegetated ditches, hedgerows, woodlots, and rural buildings. Crop phenologies can be quite detailed; cropland phenologies offer relatively few phenophases. Cropland phenologies are useful for models of land surface, weather, and climate. Crop phenologies are useful for models of crop growth and yield and field-scale hydrological and biogeochemical processes.

Few remote sensing data products are used to derive explicit phenometrics, and each of these datasets uses the VNIR (visible-to-near-infrared) spectrum [\[2\]](#page-18-1). Moreover, each of the phenologically explicit LSP products uses different methods to derive phenological metrics, resulting in different metrics for SOS and EOS [\[2\]](#page-18-1). This discrepancy is also partly due to the challenge of equating satellite derived LSP metrics to in situ observations of plant phenology, and the spatial and temporal compositing of the VNIR satellite data to minimize data gaps that result from cloud cover, atmospheric aerosols, and orbital and solar illumination constraints [\[3](#page-18-2)[,4\]](#page-18-3).

Microwave remote sensing is based on the dielectric property of materials, which is largely governed by the material's water content. Thus, microwave measurements are sensitive to vegetation and soil water content and to changes in plant biomass and soil moisture. The frequencies of microwaves emitted by the land surface are much lower than VNIR light. These longer wavelengths are less attenuated by the atmosphere, and the earth's surface constantly emits microwaves. Satellite active and passive microwave data have been successfully applied in many LSP studies such as vegetation phenology assessment [\[5](#page-18-4)[–8\]](#page-18-5), vegetation drought response [\[9](#page-18-6)[,10\]](#page-18-7), and growing season variability [\[11](#page-18-8)[,12\]](#page-18-9). Limitations of microwave LSP monitoring include very coarse spatial resolution (25 km in this study) due to the faint microwave signal emissions of land surface materials [\[1,](#page-18-0)[13\]](#page-18-10), sensitivity to radio frequency interference (RFI; [\[14,](#page-18-11)[15\]](#page-18-12)), and signal degradation or loss due to snow cover and frozen ground [\[5,](#page-18-4)[6\]](#page-18-13).

Vegetation optical depth (VOD) is a measure of aboveground vegetation canopy thickness [\[16\]](#page-18-14) that is less sensitive to dense biomass saturation, less sensitive to atmospheric contamination and solar illumination constraints, and it can have high temporal resolution  $[1,6,17]$  $[1,6,17]$  $[1,6,17]$ . VOD is directly proportional to the vegetation dielectric constant and canopy water content. VOD responds to vegetation seasonal dynamics similar to those recorded by the VNIR MODIS vegetation indices (VIs: NDVI, EVI, and LAI) and an independent bioclimatic growing season index (GSI; [\[1](#page-18-0)[,6](#page-18-13)[,18\]](#page-18-16)). VOD has been shown to track seasonal changes in croplands in spring wheat producing regions of North America and winter wheat producing areas of Volga River Basin in Russia, and heatwaves that devastated crop production in Northern Eurasia [\[19,](#page-18-17)[20\]](#page-18-18) similar to that of NDVI and EVI [\[21](#page-19-0)[,22\]](#page-19-1). VOD SOS corresponds well to

MODIS NDVI and EVI green-up dates, and SOS estimates from flux tower gross primary production (GPP) and ecosystem respiration, but with temporal offsets [\[1\]](#page-18-0).

Phenometrics derived from the downward Convex Quadratic (CxQ) model include Peak Height (PH) and Thermal Time to Peak (TTP), which are more consistent than SOS and EOS, because they are minimally affected by snow and frost and other non-vegetation related issues [\[23,](#page-19-2)[24\]](#page-19-3). PH, estimated as a quadratic function of accumulated growing degree-days (AGDD) [\[21](#page-19-0)[,22\]](#page-19-1) or accumulated relative humidity [\[25\]](#page-19-4), has been found to have significant positive correlation with agricultural production statistics for rainfed agriculture. In the application of the CxQ model, a piece of a parabola is fit to the response variable as a quadratic function of an accumulated seasonal forcing, such as AGDD. The advantage of the CxQ model is the phenometrics PH and TTP can be calculated directly from the fitted parameter coefficients. The disadvantage is that some LSP shapes are not well approximated by a parabolic curve. We observed in earlier work [\[21\]](#page-19-0) that only at the very center of the growing season were VOD cropland time series fitted well by the CxQ model. In this study, we hypothesize that VOD phenometrics characterize cropland dynamics in a manner complementary to MODIS NDVI phenometrics, but with a temporal lag. The aims of this study are: (1) to compare the VOD phenometrics TTP and PH estimated from passive microwave time series using a maximum value approach with the NDVI phenometrics TTP and PH estimated from MODIS data using the CxQ model; (2) to quantify temporal offsets between the two sets of phenometrics; (3) to interpret the origin of these offsets; and, importantly; and (4) to demonstrate the validity of the VOD approach so that these microwave phenometrics can be used in cloud-obscured areas.

#### **2. Data and Methodology**

#### *2.1. Remote Sensing Data*

We used two very different remote sensing datasets: emitted terrestrial microwave radiation and reflected solar shortwave radiation. The microwave dataset was based on the Advanced Microwave Scanning Radiometer (AMSR-E) enhanced land parameters developed by the Numerical Terradynamic Simulation Group at the University of Montana [\[26\]](#page-19-5). These parameters include near surface air temperature (ta;  $\sim$ 2 m height) and vegetation canopy transmittance (tc) at three microwave frequencies (6.925 GHz, 10.65 GHz, and 18.7 GHz). Onboard the NASA-EOS Aqua satellite, AMSR-E recorded data twice daily (daytime, ~13:30; and nighttime, ~01:30) from mid-June 2002 to October 2011, when the rotating antenna failed. The second dataset included optical reflectance data from the Moderate-resolution Imaging Spectroradiometer (MODIS). We used MODIS collection 5 level 3 data product in a 0.05 degree (~5.6 km) Climate Modeling Grid (CMG), specifically the Nadir Bidirectional Reflectance Distribution Function (BRDF)-Adjusted Reflectance (NBAR) data that combines observations from Terra and Aqua (MCD43C4; [\[27\]](#page-19-6)). NBAR provides 16-day retrievals (updated every 8 days) of surface reflectance normalized to a nadir view using BRDF models of surface anisotropy [\[28](#page-19-7)[,29\]](#page-19-8).

Croplands for this study were identified based on the International Geosphere Biosphere Programme (IGBP) global land cover classification scheme in the MODIS land cover CMG product (MCD12C1; [\[27\]](#page-19-6)), and the USDA Foreign Agriculture Service (FAS) crop layers by oblast (for Russia [\[30\]](#page-19-9), Kazakhstan [\[31\]](#page-19-10), and Ukraine [\[32\]](#page-19-11)).

We used tree cover data (ca. 2010) from the 30 m Global Land Cover dataset, which was derived from Landsat 7 ETM+ data by USGS and the Department of Geographical Sciences at University of Maryland [\[33\]](#page-19-12). We used these data to calculate the proportion of tree cover within our study sites.

#### *2.2. Study Region*

We conducted this study at the same sites identified in our companion paper [\[22\]](#page-19-1) that established the notion that the surface air temperature data retrieved from the microwave radiometers could be used instead of MODIS land surface temperature data to drive the convex quadratic model of land surface phenology (LSP). Indeed, it improved model fits, despite its coarser spatial resolution, because there was higher temporal resolution and lower variability arising from the spatial heterogeneity of the land surface. In that paper, we used AGDD from AMSR-E air temperature data, and NDVI and EVI from MODIS data to characterize cropland dynamics throughout the growing season in the study region [\[22\]](#page-19-1).

AMSR-E pixels dominated by croplands were identified through land cover stability analysis [\[22](#page-19-1)[,34\]](#page-19-13) using the MODIS IGBP Land Cover Type 1 Percentage Product (MCD12C1; [\[27\]](#page-19-6)). We identified 49 AMSR-E pixels (or study sites) across the major grain producing areas of Ukraine (UA, [1](#page-4-0)4), southern Russia (RU, 24), and northern Kazakhstan (KZ, 11) (Figures 1 and [2;](#page-4-1) [\[22\]](#page-19-1)). For contrast, we selected one AMSR-E pixel dominated by mixed forest cover (IGBP class 5) in Mari El Republic of the Russian Federation. We used this representative MFO site only for contrast and did not incorporate it into our full analyses. Where it is included, it is indicated in figure captions or accompanying text. We derived, within each study pixel, the proportions of croplands, grasslands, and cropland/natural vegetation mosaic (CNVM) using the MODIS IGBP Land Cover product (MCD12C1; [\[27\]](#page-19-6)). These classes were the three predominant land covers in the region. In addition, we calculated the tree cover proportion from the Landsat 7 ETM+ 30 m resolution Global Land Cover data [\[33\]](#page-19-12). The proportions of tree cover, open water, bare ground, and undifferentiated other classes (including croplands and grasslands) that occur within each AMSR-E study pixel appear in Figure [2.](#page-4-1) ast, we selected one AMSR-E pixel dominated by mixed forest cover (IGBP  $\epsilon$ and/natural vegetation mosaic (CNVM) using the MODIS IGBP Land Cover ; croplands and grasslands) that occur within each AMSR-E study pixel appear in  $\,$ anying text. We derived, within each study pixel, the proportions or cropianus,  ${\rm g}$ The proportions or tree cover, open water, bare ground, and undifferentiated out

<span id="page-4-1"></span>

X-axis indicates study sites numbered from lower (1) to higher (50) latitudes. Figure 1 shows the **Figure 2.** Average cropland (purple), and grassland (orange) cover in percent for 2003–2010 from the  $\sum_{i=1}^{n}$ MODIS IGBP Land Cover Type 1 Percent Product at ~5.6 km spatial resolution MCD12C1 [\[27\]](#page-19-6), and tree cover fraction (%) in 2010 from the Landsat ETM+ 30 m resolution Global Land Cover product [\[33\]](#page-19-12). X-axis indicates study sites numbered from lower (1) to higher (50) latitudes. Figure 1 shows the  $\frac{1}{2}$  distributions of the study sites and countries in which they are found. Sites are so  $s_{\text{obs}}$  are class (class  $\lambda$ ), which is not provided to  $\lambda$  and  $\lambda$   $\lambda$ largest (left) to smallest (right) cropland cover percent. Site 50 is a Mixed Forest site, in Mari El, RU. Note that summation of land cover proportions can exceed 100% at some sites, because the tree cover **Figure 2.** Average cropland (purple), and grassland (orange) cover in percent for 2003–2010 from the latitudinal distributions of the study sites and countries in which they are found. Sites are sorted from data source is different and at a different scale from the other two land cover classes. Cropland cover in  $\ddot{\text{a}}$  is the tree cover data. Land cover values  $\ddot{\text{b}}$  are labeled on the tree cover values  $\ddot{\text{b}}$ some sites might be larger than what is presented here, since the MODIS land cover data has a separate class named Cropland/Natural Vegetation Mosaic (CNVM, IGBP class 14), which is not illustrated here to avoid overlap with the tree cover data. Land cover values >5% are labeled on the respective bars. These MODIS land cover data are also used in [\[22\]](#page-19-1).

Over the eight years of the study period, the average cropland cover for all sites was 88%; in contrast, the mixed forest site was 93% mixed forest. Many sites in UA and some in RU had 100% average maximum cropland cover over the study period, while Volgograd (site 14) in RU had the minimum average cropland cover (46%, Figure [2\)](#page-4-1). Saratov 1 in RU (site 21) had the largest grassland encroachment with 69% and 31% mean cropland and grassland cover, respectively, over the eight years (Figure [2\)](#page-4-1). Thus, site 21 exhibited the largest cropland cover variation (range = 28%) [\[22\]](#page-19-1). Omsk 1 in RU (site 46), and Kostanay 2 in KZ (site 36) are other examples. The finer resolution Landsat data revealed that the MFO site (site 50) had the largest tree cover proportion (75%), followed by Volgograd (site 14, 17%).

### *2.3. Characterizing Land Surface Phenology in VODs and NDVI*

We used the AMSR-E and MODIS data from all eight years (2003–2010) for all pixels. The AMSR-E data record has winter data gaps as it was pre-filtered for snow covered or frozen land surfaces [\[35\]](#page-19-14). To avoid the frozen season and to maintain a consistent analysis period across all pixels, we restricted our focus to data from DOY 89–305, i.e., 30 March to 1 November for non-leap years and 29 March to 31 October for leap years. An 8-day forward moving average filter was applied to the AMSR-E data to minimize data gaps due to orbit and swath width, and to align the AMSR-E data with the corresponding compositing periods of the MODIS NBAR data (MCD43C4) (Figure [3\)](#page-6-0). Growing degree-day (GDD) is the daily thermal time increment above a certain threshold (base temperature) for plant growth [\[36–](#page-19-15)[38\]](#page-19-16), and accumulated growing degree-days (AGDD) are the summation of daily thermal time increments throughout the whole growing period [\[24](#page-19-3)[,39,](#page-19-17)[40\]](#page-19-18). In other words, the passage of days is weighted by the quantity of growing degrees occurring that day, with zero (but not negative) degrees being a permissible weight [\[41\]](#page-19-19). McMaster [\[42\]](#page-19-20) concluded that the base temperature of  $0^{\circ}$ C is a robust and sufficient threshold for wheat phenology, which is the main crop in our study region. GDD was calculated from the AMSR-E air temperature (ta) data with a base temperature of 273.15 K  $(=0 °C)$  as follows:

GDD = max
$$
[\frac{t_{\text{ASC}} + t_{\text{DES}}}{2} - 273.15, 0]
$$
 (1)

where  $t_{\text{ASC}}$  and  $t_{\text{DES}}$  are ascending and descending pass temperatures, which roughly corresponds to the daytime (~13:30) and nighttime (~22:30) temperatures, respectively. We applied an 8-day forward moving summation to the GDDs and picked up those values corresponded with the MODIS reflectance data (MCD43C4) acquisition dates to mimic the whole growing season GDD (DOY 89–305 in this case) and to align it with the MODIS data. Thus, each annual growing period has 28 GDD values. These GDD values were accumulated to yield AGDD.

$$
AGDDt = AGDDt-1 + GDDt
$$
 (2)

where GDD*t* is daily temperature increment of growing degree days at time *t*.

Daily GDD from AMSR-E tracked seasonal, weekly and monthly dynamics of corresponding weather station GDD [\[22\]](#page-19-1). The root mean square deviation (RMSD) between these daily datasets from the two sources was very low, 1.86–3.16 ◦C [\[22\]](#page-19-1). Linear regression of AMSR-E GDD with weather station GDD on these cropland sites yielded  $\mathbb{R}^2 > 0.82$  [\[22\]](#page-19-1). This result is in line with Jones et al. [\[43\]](#page-19-21) who found a bias of 1.0–3.5 K between WMO weather station and AMSR-E daily air temperature data on vegetated lands across the Northern Hemisphere.

NDVI was calculated from the MODIS NBAR reflectance data using the standard formula by Tucker [\[44\]](#page-20-0). NDVI was calculated for each 0.05-degree (~5.6 km) pixel and zonal-averaged to the 0.25-degree (25 km) AMSR-E study pixels. We fitted the MODIS NDVI as a function of AMSR-E AGDD using the downward CxQ model.

$$
NDVI_t = \alpha + \beta \times AGDD_t - \gamma \times AGDD_t^2
$$
 (3)

The intercept  $\alpha$  is the background NDVI at the start of observation period, the linear parameter  $\beta$ affects the slope, and the quadratic parameter  $\gamma$  controls the curvature. Since the model is downward convex quadratic, the sign of β coefficient is positive and γ coefficient is negative. *Remote Sens.* **2017**, *9*, 613 6 of 20

Two phenometrics were derived from the fitted parameter coefficients of the CxQ model. These Two phenometrics were derived from the fitted parameter coefficients of the CxQ model. These are Peak Height NDVI (PH; Equation (4)) and Thermal Time to Peak NDVI (TTP<sub>NDVI</sub>; Equation (5)):<br>

$$
PH = \alpha - (\beta^2 / 4 \times \gamma) \tag{4}
$$

$$
TTP_{NDVI} = -\beta / 2 \times \gamma
$$
 (5)

where  $\alpha$ ,  $\beta$ , and  $\gamma$  are the fitted parameter coefficients.

Vegetation Optical Depth (VOD) was derived as a negative natural logarithm of vegetation Vegetation Optical Depth (VOD) was derived as a negative natural logarithm of vegetation transmittance [VOD =  $-\log_e$ (tc) =  $-\ln$ (tc)]. In a previous study [\[21\]](#page-19-0), we fitted the core growing season VODs from the three microwave frequencies (6.925 GHz, 10.65 GHz, and 18.7 GHz) using the  $CxQ$  model in a two-step process. The fits in that study were good (coefficients of determination were larger than 0.90 ( $\mathbb{R}^2 > 0.90$ ) in time and space) but limited to around the peak of the growing season. Here, however, we need to consider a larger fraction of the growing season; thus, we needed season. Here, however, we need to consider a larger fraction of the growing season; thus, we needed<br>a different approach. The VOD shapes for the entire growing season are not well fitted using the CxQ model. VOD is sensitive to aboveground biomass structure, including crop residues, and to the model. VOD is sensitive to aboveground biomass structure, including crop residues, and to the vegetation water content found in entire aboveground biomass, while NDVI is sensitive primarily to vegetation water content found in entire aboveground biomass, while NDVI is sensitive primarily to vegetation greenness. VOD has a different seasonal progression shape that is not suitably captured by vegetation greenness. VOD has a different seasonal progression shape that is not suitably captured by<br>a quadratic curve compared to that of NDVI. Therefore, we used the maximum VOD value approach to determine cropland vegetation PH and TTP. That is, the observed maximum VOD value was taken as PH VOD, while the corresponding AGDD was taken as TTP. Similar approach was also used for the NDVI for a direct comparison with the CxQ model fit derived PH and TTP NDVI. The PH NDVI and PH VOD values were regressed to see the relationship between cropland peak greenness and peak biomass and water content. We then used analysis of covariance (ANCOVA) to test whether the peak biomass and water content. We then used analysis of covariance (ANCOVA) to test whether the<br>slopes and/or intercepts from the linear regression model fit were significantly different by microwave frequency: the microwave frequencies (6.925, 10.65, and 18.7 GHz) were the independent categorical frequency: the microwave frequencies (6.925, 10.65, and 18.7 GHz) were the independent categorical<br>effect variables, the peak greenness was covariate, and PH VOD was the response variable. The first statistical assumption for ANCOVA is that the covariate (peak greenness in our case) is uncorrelated with other independent variables (microwave frequencies), and the second assumption is that the covariate (peak greenness) is correlated with the dependent variable (PH VOD; [\[45\]](#page-20-1)). In all cases,  $p \leq 0.05$  was considered significant.

### **3. Results**

#### *3.1. Time Series Land Surface Phenologies of NDVI and VODs*

All three VOD time series were able to capture the seasonality of croplands (both bimodal patterns and unimodal patterns), similar to MODIS NDVI (Figure [4\)](#page-7-0). The bimodality arises from the planting *Remote Sens.* **2017**, *9*, 613 7 of 20 of winter grains in the fall, and growth and harvest in the subsequent early summer. After snow melts, croplands are primarily barren or contain crop residues (non-photosynthetic biomass) prior to tilling and planting. Green-up occurs after seed germination at emergence (initiation of visible aboveground growth) but prior to significant aboveground biomass accumulation. This pattern is evident in Figures [4](#page-7-0) and [5,](#page-8-0) where the rise in VOD occurs later than NDVI. Cropland peak VODs, which are sensitive to aboveground vegetation water content and biomass, consistently lagged in time and space from the peak NDVI, which is sensitive to vegetation greenness and leaf area index (Figures [4](#page-7-0) eparts from the peak NDVI, which is sensitive to vegetation geocrates and fear and fract (1 gares 1 and [5\)](#page-8-0). Furthermore, the VODs showed slower senescence, likely a consequence of residual biomass (crop residue) following harvest. VOD PH for sites with  $\geq$ 10% tree cover were not significantly different from sites with  $\geq$ 99% croplands at  $\alpha$  = 0.05 and  $p > 0.05$  (Figures 4 and [5\)](#page-8-0) [\[46,](#page-20-2)[47\]](#page-20-3). Higher microwave frequencies exhibit higher dynamic range: the shorter wavelengths are more attenuated by vegetatio[n ca](#page-7-0)no[py](#page-8-0) (Figures 4 and 5).  $\sigma$ , Furthermore, the VODs showed slower senescence, likely a consequence of residual biometerm

<span id="page-7-0"></span>

**Figure 4.** VOD time series for the three microwave frequencies: green pluses = 18.7; purple circles = **Figure 4.** VOD time series for the three microwave frequencies: green pluses = 18.7; purple circles = 10.65; orange triangles = 6.925 GHz; and blue diamonds = NDVI. Selected series arranged from south to north of our study region: (**a**) Stavropol, RU, site 2; (**b**) Kirovohrad, UA, site 15; (**c**) Petropavlovsk 3, KZ, site 42; and (**d**) Kazan, RU, site 49; and (**e**) Mari El, RU, site 50 (MFO site included for contrast). Note that the VOD range for the MFO site is higher (0.2–1.9) than the range for the cropland sites (0.2–1.6).

<span id="page-8-0"></span>

**Figure 5.** VODs in three microwave frequencies (green squares = 18.7, purple circles = 10.65, and **Figure 5.** VODs in three microwave frequencies (green squares = 18.7, purple circles = 10.65, and orange triangles = 6.925 GHz) and NDVI (blue diamonds) interannual variability of a southern study orange triangles = 6.925 GHz) and NDVI (blue diamonds) interannual variability of a southern study<br>site (Simferopol, UA, 45.6°N) for 2003–2010. The 6.925 GHz vegetation transmissivity was missing from the source dataset in 2004. Seasonal patterns changed from bimodal (2003–2004) to unimodal from the source dataset in 2004. Seasonal patterns changed from bimodal (2003–2004) to unimodal (2005–2009) and back to bimodal (2010). (2005–2009) and back to bimodal (2010).

LSPs at the lower latitudes within the region exhibit longer and/or bimodal patterns arising from the cultivation of winter grains (Figure [4a](#page-7-0),b). On the other hand, LSPs at the higher latitudes exhibit shorter unimodal growing season due to cultivation of spring grains (Figure [4c](#page-7-0),d). At each study site, the VOD and NDVI exhibit similar seasonal patterns, amid interannual variation. For example, in Petropavlovsk 3, KZ (Figure [4c](#page-7-0)), in 2003 there was high and earlier peak LSPs in fewer AGDD, while in 2010 there was lower and flatter peak in more AGDD, due to the 2010 heatwave affecting European Russia [\[19](#page-18-17)[,20\]](#page-18-18). Note the 2007 VOD in Kirovohrad, UA (Figure [4b](#page-7-0)) is almost flattened compared to other years, due to the devastation of crops by the 2007 heatwave in Ukraine [\[48\]](#page-20-4). The heatwave effect is more evident on the VODs compared to their counterpart NDVI (Figure [4b](#page-7-0)), due to the sensitivity of VODs to vegetation water content. The Mari El mixed forest site in Russia displayed a distinct LSP in magnitude and shape compared to the rest of the 49 cropland sites (Figure [4e](#page-7-0)). Both VOD and NDVI were larger in magnitude (note the y-scales) and flatter in shape. The VODs in particular showed a much-delayed senescence compared to the NDVI. The magnitude and peak timing of VOD were found sensitive to woody plant foliage, whereas NDVI seasonality was governed by the green herbaceous vegetation [\[49](#page-20-5)[–51\]](#page-20-6).

Figure 5 shows Time series of VODs and NDVIs in a southern study site (Simferopol, UA) that experienced alternate unimodal and bimodal seasonal patterns over the eight years. All three<br> microwave frequencies VOD were able to capture these LSP patterns similar to their counterpart NDVI, despite some differences in magnitude and shape.

## 3.2. Thermal Time to Peak and Peak Height NDVI and VOD Phenometrics  $10<sub>0</sub>$

In this section, we present  $TTP_{NDVI}$  and  $PH_{NDVI}$  derived from the CxQ model, followed by nonparametric phenometrics for VOD and NDVI determined from the growing season maxima.

## 3.2.1. The CxQ Model Derived NDVI Phenometrics  $\sum_{i=1}^{n}$  in the expansion  $E$  in the growing season in the lower latitudes in t

The NDVI CxQ model fits for all sites are high with  $0.78 < R^2 < 0.99$ . Sample fits appear in Figure 6. Sites at lower latitudes that can support double growing season attain their first peaks at the earliest (<1000 AGDD, e.g., Figure 6d, Cherkessk, RU, 44°); moving farther north, the seasonal pattern shifts<br>from bimodal to unimodal, and the TTP<sub>NDVI</sub> is pushed up further to the growing season (between<br>1000 and 2000 AGDD, e.g., from bimodal to unimodal, and the  $TTP<sub>NDU</sub>$  is pushed up further to the growing season (between 1000 and 2000 AGDD, e.g., Figure 6c, Zaporiyhzhya 1, UA, 48° and Figure 6b, Kokshetau 1, KZ, 53°). Moving towards the northern study sites, the TTP starts to decrease to 1000 AGDD due to the thermal limitation and shorter growing season (e.g., Figure 6a, Cheboksary, RU, 56°). Figure 7 presented the general relationship of TTP<sub>NDVI</sub> as a function of latitude for all sites. Note also the NDVI CxQ fit Mov[ing](#page-9-0) towards the northern study sites, the TTP starts to decrease to 1000 AGDD due to the thermal<br>limitation [a](#page-9-0)nd shorter growing season (e.g., Figure 6a, Cheboksary, RU, 56°). Figure 7 presented the<br>general relationship Figure 6d) starts a bit earlier than the time we considered in this study (DOY 89 = March 30 (March 29)<br>in leap years)). in leap years)).

<span id="page-9-0"></span>

**Figure 6.** Average NDVI (2003–2010) as a function of AGDD for cropland sites that encompass the **Figure 6.** Average NDVI (2003–2010) as a function of AGDD for cropland sites that encompass the whole latitudinal range: (a) 48, RU; (b) 28, KZ; (c) 11, UA; and (d) 1, RU. Coefficients of determination  $(R<sup>2</sup>)$  for these sites ranged from 0.88 to 0.97.

<span id="page-10-0"></span>

Figure 7. Scatterplot for TTPNDVI as a function of latitude fitted with a convex quadratic model. There is a significant positive relationship ( $R^2$  = 0.50): as latitude increased, TTP<sub>NDVI</sub> increased in lower latitudes to certain limit and then declined in the northernmost study sites (54-56°N latitude).

Average (2003–2010) PH<sub>NDVI</sub> phenology metric in our study croplands ranged between 0.58 and  $0.84$  (not shown here). NDVI at half-TTP (NAHT) as a function of  $PH<sub>NDVI</sub>$  displayed a distinct trend indicating that NDVI in these sites is driven by local climate (Figure [8a](#page-10-1)). Generally, lower latitude study sites have gentler NDVI gradient time series with longer growing season compared to the steeper NDVI gradient of the shorter summer growing season at higher latitudes. Thus, the difference between PH<sub>NDVI</sub> and NDVI at half-TTP increased as latitude increases, yielding a strong linear fit with  $R^2 = 0.81$  (Figure 8a). However, the PH<sub>NDVI</sub> as a function of latitude di[d](#page-10-1) not show a clear trend (Figure [8b](#page-10-1)). Temperature dominates crop growth from spring to summer, while other variables (such  $\frac{1}{2}$  example  $\frac{1}{2}$  have only at  $\frac{1}{2}$  are  $\frac{1}{2}$  are  $\frac{1}{2}$  are  $\frac{1}{2}$ . As the winter grains  $\frac{1}{2}$  area  $\frac{1}{2}$  and  $\frac{1}{2}$  area  $\frac{1}{2}$  area  $\frac{1}{2}$  and  $\frac{1}{2}$  area  $\frac{1}{2}$  and  $\frac{$ as rainfall) play roles that are more important in crop production.

<span id="page-10-1"></span>

**Figure 8.** Scatterplot for: PH<sub>NDVI</sub> minus NDVI at half-TTP (NAHT) as a function of latitude (a); and PH<sub>NDVI</sub> as a function of latitude (**b**). Both are fitted with linear trend line yielding strong correspondence for the former ( $R^2 = 0.81$ ), but no clear correspondence for the latter ( $R^2 = 0.07$ ).

green circles in upper right corner) displayed strong correspondence with  $R^2$  = 0.94. In contrast, the due to the fact that crops are annual vegetation and due to possible crop and land rotation annually PHNDVI as a function of latitude (**b**). Both are fitted with linear trend line yielding strong or every few years. Moreover, croplands are more vulnerable to climatic variability compared to The NAHT as a function of  $PH<sub>NDUI</sub>$ , for selected sites that were more impacted by the 2003, 2007, and/or 2010 heatwaves, showed a positive correspondence (Figure [9b](#page-11-0)). The two phenometrics for the mixed forest in the most northern study site Mari El, Russia (site 50 appears as the outlying correspondence between these phenometrics for croplands exhibited more interannual variability.

the perennial mixed forests. The southern study sites exhibited smaller NAHT and  $PH<sub>NDVI</sub>$  in 2003 due to minimal effect of the European heatwave on croplands in the study area [\[52\]](#page-20-7). As the winter grains were affected many croplands were sown to spring grains and, therefore, many southern study croplands in 2003 exhibited the double seasonality. The affected winter croplands (first peak) exhibit smaller NAHT and PH<sub>NDVI</sub> (Figure [9b](#page-11-0) sites 1, 2, 4, and 13). However, the smaller values for the two phenometrics were recorded in 2010 for the northern study sites, due to the effect of the 2010 Russian heatwave, which also impacted northern Kazakhstan (Figure [9b](#page-11-0), sites 13, 24, and 36) [\[19](#page-18-17)[,20\]](#page-18-18). As forests are perennial and resilient to climatic variability, the two phenometrics in Mari El, Russia were not that affected by the 2010 Russian heatwave and displayed closer values consistent trend throughout the study period. The 2010 NAHT as a function of  $PH_{NDVI}$  for this mixed forest site was just about at an average position of the other seven years of values (Figure [9b](#page-11-0)).

<span id="page-11-0"></span>

Figure 9. Annual phenometrics of NAHT as a function of PHNDVI: (a) for all study sites; and (b) selected study sites for 2003–2010. Sites are numbered according to their latitudinal position from south (1) to north (50) (Figure [1\)](#page-4-0).

## 3.2.2. The Maximum Value Approach for VOD Phenometrics 3.2.2. The Maximum Value Approach for VOD Phenometrics

For the land surface phenology of VOD, Figure  $10$  presents the  $PH<sub>VOD</sub>$  as a function of the corresponding  $TTP_{VOD}$  for all sites. In the study sites dominated by croplands,  $PH_{VOD}$  ranged between 0.85 and 1.74, while the  $PH<sub>NDVI</sub>$  (also calculated using the maximum value approach) ranged between 0.60 and 0.83. The ordering of the  $PH<sub>VOD</sub>$  magnitude from high to low was 18.7 GHz > 10.65 GHz > 6.925 GHz: the higher the frequency, the higher the attenuation by vegetation, and, thus, the larger the VOD magnitude. The PH<sub>VOD</sub> lags the PH<sub>NDVI</sub>, because the PH<sub>VOD</sub> responds to vegetation water content and aboveground biomass, which both continue to increase after the apparent peak absorption of photosynthetically active radiation, which is captured by the PHNDVI. Generally, the shorter the microwave wavelength, the later the PH<sub>VOD</sub> occurs in terms of AGDD. The lag between the PH<sub>VOD</sub> for 10.65 and 18.7 GHz was narrower than between the PH<sub>VOD</sub> for 6.925 GHz from the other two. We have presented a quantified lag graph (Figure 11b) among the maximum value determined two. We have presented a quantified lag graph (Figure [11b](#page-12-1)) among the maximum value determined PH VODs and the CxQ model derived PH NDVI in Section [4.1.](#page-12-2)

<span id="page-12-3"></span><span id="page-12-0"></span>

<span id="page-12-4"></span><span id="page-12-1"></span>**Figure 10.** Scatter plot of the maximum value approach determined PH VODs and NDVI as a function **Figure 10.** Scatter plot of the maximum value approach determined PH VODs and NDVI as a function of their corresponding TTP. Note the magnitude of the VODs and NDVI PHs; VODs PH lagged their of their corresponding TTP. Note the magnitude of the VODs and NDVI PHs; VODs PH lagged their counterpart NDVI PH; and also the lag among the VODs PH relative to their microwave frequency.

Figure 11. Scatterplots and linear regression fits of the CxQ model derived PH<sub>NDVI</sub> and maximum value determined PH<sub>VOD</sub> at three microwave frequencies (6.925 GHz (orange triangles), 10.65 GHz (purple circles), and 18.7 GHz (green plus)) for 2003–2010. The PH linear fits for two datasets were (purple circles), and 18.7 GHz (green plus)) for 2003–2010. The PH linear fits for two datasets were  $h = \frac{1}{2}$ high with coefficients of determination of 0.77, 0.84, and 0.78 for the 6.925, 10.65, and 18.7  $\text{GHz}$ frequencies, respectively.

#### **4. Discussion**

## <span id="page-12-2"></span>Peak heights are less likely to be affected by snow and other non-vegetation related issues *4.1. VOD and NDVI Peak Heights: Correlations and Biases*

Peak heights are less likely to be affected by snow and other non-vegetation related issues agricultural production  $\frac{25}{25}$ . The PHVOD derived using the maximum value approach correspondence approach correspondence approach correspondence approach correspondence approach correspondence approach correspondenc compared to the start-of-season (SOS)  $[23,24]$  $[23,24]$ . PH<sub>NDVI</sub> has significant positive correlation to agricultural production [\[25\]](#page-19-4). The  $\rm PH_{VOD}$  derived using the maximum value approach corresponded favorably with the PH<sub>NDVI</sub> derived using the CxQ model. The 10.65 GHz PH<sub>VOD</sub> achieved the highest correspondence with the PH<sub>NDVI</sub> with a high coefficient of determination ( $R^2$  = 0.84) and the lowest standard error (SEE = 0.1275; Table [1,](#page-14-0) Figure [11\)](#page-12-1). PH for the eight years' average VOD and NDVI for all cropland sites except Saratov 1 (which had a significant proportion (31%) of grassland), were considered in this analysis.

Two hypotheses were tested using analysis of covariance (ANCOVA). First, the covariate (peak We hypotheses were rested asing analysis of covariance (Table 211). They are covariant greenness) was not significantly (at  $\alpha$  = 0.05) correlated to the independent variable (microwave frequency) [\[45\]](#page-20-1). ANCOVA revealed the slopes resulting from the linear fits between  $PH_{NDVI}$  and  $\rm PH_{VOD}$  did not differ significantly between pairs of microwave frequencies (Table [2\)](#page-14-1). The intercepts were significantly different, given the different magnitudes of the VODs. On global, annual scales,

AMSR-E VOD was found more highly correlated with MODIS VI's compared to anther passive microwave data, Soil Moisture and Ocean Salinity (SMOS) VOD did with the MODIS VI's [\[53\]](#page-20-8). Second, the covariate  $PH<sub>NDVI</sub>$  was correlated with response variable  $PH<sub>VOD</sub>$  as described in the previous paragraph and in Table [1](#page-14-0) and Figure [11](#page-12-1) [\[45\]](#page-20-1). The interpretation from the fulfilment of these two ANCOVA assumptions is that peak greenness ( $PH<sub>NDVI</sub>$ ) had a significant and positive effect on  $PH<sub>VOD</sub>$ and the effect is similar for all three microwave frequencies (the effect of  $PH<sub>NDVI</sub>$  on  $PH<sub>VOD</sub>$  did not depend on microwave frequency).

Even though PH<sub>NDVI</sub> and PH<sub>VOD</sub> have significant positive correspondence, the latter lagged the former (Figure [12b](#page-13-0)). This behavior was expected since microwaves are differentially sensitive to aboveground biomass and canopy water content; in contrast, the VNIR is differentially sensitive to photosynthetically active radiation (PAR) absorption. The peak VOD lags the peak greenness by several n<br>weeks following delayed increases in vegetation water content and development of aboveground biomass. Average VOD lag for all study years and sites was about three weeks, but it varied in time and space, and by microwave frequency (Figure [12b](#page-13-0)). We have also presented the PH $_{\rm VOD}$  and PH $_{\rm NDVI}$  as a function of their respective TTP metric in Figure [12a](#page-13-0) for ease of interpretation of the lags in Figure [12b](#page-13-0). The temporal and spatial average  $PH<sub>VOD</sub>$  lag increases as microwave frequency increases. The 6.925, 10.65, and 18.7 GHz  $\rm PH_{VOD}$  average lags are 1.9, 2.2 and 2.7 weeks, respectively, relative to the peak greenness (Figure [12b](#page-13-0) and Table [A1\)](#page-17-0).  $\rm PH_{NDVI}$  lags  $\rm PH_{VOD}$  6.925 GHz at three sites only. Few sites that showed PH $_{\rm NDVI}$  temporal average lag to that of the PH $_{\rm VOD}$ —three sites for the 6.925, one site for the 10.65 and one site for the 18.7 GHz PH<sub>VOD</sub> over the study period (all lags less than a week). Across the 50 sites the average temporal lag of PH<sub>VOD</sub> relative to PH<sub>NDVI</sub> ranges from  $-0.8$  to +5.1 weeks for  $6.925$  GHz, from  $-0.1$  to  $6.7$  weeks for  $10.65$  GHz, and from  $-0.9$  to  $7.2$  weeks for  $18.7$  GHz.  $\frac{1}{100}$  and  $\frac{1}{100}$  are the from  $\frac{1}{100}$  to  $\frac{1}{100}$  and  $\frac{1}{100}$  and  $\frac{1}{100}$  and  $\frac{1}{100}$  and  $\frac{1}{100}$  and  $\frac{1}{100}$  $\frac{1}{2}$  model derived peak green  $\frac{1}{\sqrt{2}}$  in a verify that  $\frac{1}{\sqrt{2}}$  or  $\frac{1}{\sqrt{2}}$  is 12.9 weeks (mean  $\frac{1}{\sqrt{2}}$  or  $\frac{1}{\sqrt{2}}$  o

<span id="page-13-0"></span>

 $\frac{1}{2}$  function  $\frac{1}{2}$ ;  $\frac{1}{2}$   $\frac{1}{2}$   $\frac{1}{2}$  and  $\frac{1}{2}$   $\frac{1}{2$ **Figure 12.** Scatterplots of: (**a**) the PH<sub>VOD</sub> determined by maximum value and the PH<sub>NDVI</sub> from the CxQ<br>model as a function of their corresponding TTP; and (**b**) PH<sub>VOD</sub> lags relative to their corresponding PH<sub>NDVI</sub> as a function of the respective TTP VODs. Details can be found in Table  $A1$ .

To check the usefulness of the maximum value-based PH phenometrics determination approach, we correlated PH<sub>NDVI</sub> determined using this approach with that of the CxQ model. The PH<sub>NDVI</sub> from

the two methods showed a strong linear relationship with an  $R^2$  of 0.86 (Figure [13\)](#page-14-2). However, the CxQ model derived peak greenness lags the maximum-value determined peak greenness. On average, the CxQ model derived  $PH<sub>NDVI</sub>$  lags the maximum-value determined  $PH<sub>NDVI</sub>$  by one week. Therefore, there was a general underestimation of the  $PH<sub>VOD</sub>$  lags by about one week. On an ecoregional scale, studying AMSR-E SOS and MODIS green-up onset dates in North America, Jones et al. [\[1\]](#page-18-0) found a correspondence between VOD SOS and green-up onset dates with  $R^2 = 0.45$  for VOD and NDVI, and  $R^2$  = 0.48 for VOD and LAI. In cropland dominated ecoregions (63% cropland) in North America, VOD *Remote Sens.*  SOS lagged by 5.7 to 12.9 weeks (mean = 8.6) compared to the NDVI green-up onset date [\[54\]](#page-20-9). **2017**, *9*, 613 14 of 20

## and the 2007 heatwave affecting Ukraine [48]. Here, the heatwave effects on croplands were revealed *4.2. Heatwave Responses of VODs and NDVI*

In our previous work [\[21,](#page-19-0)[22\]](#page-19-1), we have noted the 2010 heatwave affecting Russia and Kazakhstan [\[19,](#page-18-17)[20\]](#page-18-18) and the 2007 heatwave affecting Ukraine [\[48\]](#page-20-4). Here, the heatwave effects on examinations (25, 20) and are not continuous anticoming community (20). The relative comparison of the two croplands were revealed by the time series of VODs and NDVIs, the relative comparison of the two LSP measures, and the model derived phenometrics  $PH<sub>NDVI</sub>$  and NAHT. During the heatwave years, compared to the interpretation of the interpretation  $\frac{N}{N}$  responds to  $\frac{N}{N}$  for the VODs and NDVIs were well below the average VOD and NDVI for non-heatwave years, as

croplands were negatively impacted by the excess heatwave (Figure [14\)](#page-15-0). Heatwave years were more evident in the VODs compared to their counterpart NDVIs, since VOD strongly responds to vegetation water content. The difference of the VOD data during the heatwave years to the average non-heatwave years VOD was found significantly different (*p* < 0.001) from that of the similarly analyzed NDVI data (Figure [14\)](#page-15-0). The CxQ model derived NAHT as a function of  $PH<sub>NDVI</sub>$  for sites affected by the 2010 heatwave was lower relative to the other non-heatwave years (Figure [15a](#page-15-1)). The difference between the  $PH<sub>NDVI</sub>$  and NAHT for the 2010 data was found significantly different ( $p < 0.001$ ) from the average of the 2003–2009 data (Figure [15b](#page-15-1)). The marker in the upper-right corner of figure 15a is the mixed forest site in Mari El, Russia, showing little effect of the heatwave at that site. *Remote Sens.* **2017**, *9*, 613 15 of 20

Conclusions and Recommendations** In this paper, we have compared and contrasted the peak time peak time peak time peak time of contrasted the peak times of contrasted t

In this paper, we have compared and contrasted the peak timing of cropland vegetation maturity using two complementary remote sensing datasets. Time series of LSP of VOD at three microwave  $\mathcal{L}$  similar to but different from that of the VNIR MODIS NDVI. A higher that of the VNIR MODIS NDVI. A higher that  $\mathcal{L}$ 

frequencies—6.925, 10.65, and 18.7 GHz—from the passive Advanced Microwave Scanning Radiometer on EOS (AMSR-E) was able to capture the seasonality of croplands (both bimodal and unimodal seasonal patterns) similar to but different from that of the VNIR MODIS NDVI. A higher microwave frequency generates a higher VOD, since smaller wavelengths are more quickly attenuated by aboveground vegetation.

The timing and magnitude of the growing season peak (TTP and PH) are more consistent quantitative cropland phenometrics, in large part because they are minimally affected by snow or frost, unlike the commonly-used but ill-defined phenometrics of Start of Season and End of Season. The vegetation optical depth (VOD) retrieved from passive microwave data appears to be more robust to atmospheric effects and biomass saturation than the phenometrics based on the NDVI.

We have also demonstrated the application of the downward convex quadratic (CxQ) function to model cropland dynamics using MODIS NDVI yielding strong fits  $(0.78 < R^2 < 0.99)$ . However, the shape of the VOD time series curve shape was more complicated than a simple quadratic fit. The passive microwave AMSR-E PH<sub>VOD</sub> determined using the growing season maximum value of the growing season approach favorably corresponded with that of the VNIR MODIS peak greenness (PH<sub>NDVI</sub>) derived using the CxQ model over the study domain with  $R^2$  between 0.77 and 0.84. Although the 10.65 GHz PH<sub>VOD</sub> exhibited the best linear regression fit ( $R^2$  = 0.84) and with lowest standard error ( $SE = 0.128$ ) with the PH<sub>NDVI</sub>, the ANCOVA model analysis revealed that the slopes resulting from the linear regression fits were not significantly different by microwave frequency. In contrast, the intercepts from the ANCOVA analysis were significantly different: not surprising given the different dynamic ranges of the VODs.

Despite the strong correspondence between peak LSPs of the two datasets, there was a general lag of AMSR-E PH<sub>VOD</sub> by two weeks compared to that of MODIS PH<sub>NDVI</sub>. Based on PH<sub>NDVI</sub> analysis of same dataset using the two procedures, we found a one-week bias between the two methods, translating into a lag of three weeks between  $PH<sub>NDVI</sub>$  and  $PH<sub>VOD</sub>$ . We conclude that maximum value based PH<sub>VOD</sub> can yield phenometrics complementary to the model based PH<sub>NDVI</sub>, especially in cloud and aerosol obscured parts of the world.

The unsuitability of the CxQ model for characterizing the VOD curves and deriving simple phenometrics limits the generalizability of the  $CxQ$  model. Moreover, determining the  $PH<sub>VOD</sub>$ phenometrics using the seasonal maximum value could introduce error, when maxima result from noise. With this caveat and keeping the lag, we find the passive microwave PH<sub>VOD</sub> to complement well the VNIR PH<sub>NDVI</sub>. However, further research is needed to evaluate how best to use this complementarity for monitoring cropland dynamics and forecasting agricultural crop production, particularly in data sparse, cloud-obscured, and food-insecure parts of the world.

Although the AMSR-E ceased to function in October 2011 due to antenna failure, its legacy has been continued since May 2012 by AMSR2, an improved version of AMSR-E but with similar functionality since May 2012 [\[55\]](#page-20-10). A new blended passive microwave dataset spans the gap between the two sensors by the Microwave Radiation Imager (MWRI) sensor data on-board the Chinese FengYun 3B (FY3B) satellite [\[55](#page-20-10)[,56\]](#page-20-11). Our next step is to evaluate the use of these passive microwave data to characterize the croplands dynamics in cloud-obscured East Africa and explore linkages to agricultural crop production.

**Acknowledgments:** This research was supported in part through the NASA Earth and Space Sciences Fellowship program (NNX13AN58H), and the NASA LCLUC (NNX11AB77G) and Science of Terra and Aqua (NNX14AJ32G) programs. The AMSR-E data were accessed from Numerical Terradynamic Simulation Group (NTSG) website [\(www.ntsg.umt.edu/project/amsrelp\)](www.ntsg.umt.edu/project/amsrelp). The MODIS data were obtained from the NASA/USGS Land Processes Distributed Active Archive Center (LP DAAC) [\(https://lpdaac.usgs.gov/products/modis\\_products\\_Table\)](https://lpdaac.usgs.gov/products/modis_products_Table). Thanks especially to John Kimball for his continuing advice.

**Author Contributions:** W.G.A. and G.M.H conceived and designed the experiments; W.G.A. performed the experiments; W.G.A. and G.M.H. analyzed the data; and W.G.A. and G.M.H. wrote the paper.

**Conflicts of Interest:** The authors declare no conflict of interest.
