Corn Rootworm in South Dakota

B. H. Kantack, Extension entomologist; David Walgenbach, entomologist, Agricultural Experiment Station; and W. L. Berndt, Extension pesticide specialist.

Corn rootworms are the most serious insect problem in South Dakota. The western, northern, and southern species have been present for a number of years. Farmers can expect damaging corn rootworm infestations in fields where corn is grown continuously. Less predictable rootworm damage has also occurred in corn following small grains and flax. General observations have shown that volunteer small grain and a number of weed species are attractive as feeding sites for the adults and that egg laying also occurs in these areas. The severity of first year corn rootworm problems has also been associated with condition of the corn during August and early September as influenced by drought and frost.

Life Cycle

Adult corn rootworm beetles lay eggs in the soil of corn fields and to a lesser extent in other fields where weeds and flowering plants are present. They deposit eggs during late summer and fall. Most eggs are found in the first six inches of soil, although they also have been found to depths up to 15 inches.

The life cycle of the western corn rootworm is shown in Figure 1. This insect passes the winter in the egg stage and hatching begins in June. It requires several weeks for all eggs to hatch, so larvae of all sizes can be found during late June and early July (Figure 2).

Larvae feed on the root system, eating smaller roots and tunneling into larger ones. Even the base of the stalk below the soil surface often is severely damaged. When the larvae are full grown they change into an inactive stage called pupae.

Following pupation in the soil, the western corn rootworm adults begin to emerge in early July and continue to emerge until early September.

The northern corn rootworm's life cycle is similar to that of the western species, but usually the eggs hatch and the adult beetles emerge a little later in the season.

The southern corn rootworm — commonly known as the spotted cucumber beetle — overwinters as an adult in southern states and deposits eggs in the corn fields in spring. There may be several generations of this insect in a year. This species has been found to attack sorghum in Nebraska. Serious economic populations of southern corn rootworm have not been encountered on South Dakota corn or sorghum.

Larval Damage

Root injury results from larval feeding; smaller roots often are consumed completely, and larger roots are tunneled severely (Figure 3). Disease organisms often follow injury by rootworm larvae, causing further destruction of the root system. Most severe damage usually occurs during the latter part of June and the first three weeks in July. The entire root system is often destroyed.

Losses resulting from a rootworm infestation may range from a light yield reduction to total loss of the crop, depending on a number of factors: number of larvae per plant, time of planting, moisture conditions during and following rootworm attack, and general growing conditions.

Yield losses are considerably greater when moisture is deficient during the period of maximum larval feeding. Under these conditions root regrowth is minimal. Infested fields often become severely lodged, making mechanical harvesting operations difficult and inefficient.

Future Control Problems

The future direction and problems in corn rootworm control include several pathways. All are contained in the genetic potential and diversity of western and northern corn rootworms. The emergence of these genetically different populations will cause changes in control techniques and chemicals that are associated with selective mortality pressures. Some of these changes will be due to widespread use of given insecticides creating tolerant or resistant populations. Other changes in rootworm reaction to control measures will be caused by environmental selection; a selective mortality due to weather and soil conditions at critical stages in the rootworm life cycle. Farmers also have a role in these population changes as differential mortality can be expected from fall or spring plowing; subsequent tillage operations; and late vs. early planting dates. These factors interact and change from field to field and certainly change on an annual basis.

Information has been obtained on the various stages in the rootworm life cycle that shows a wide range of adaptability. It is possible that as the rootworm population shifts because of environmental pressures, changes also occur in their susceptibility to insecticides. Some of the physiological variations that have been observed include a segment of the rootworm population that lays eggs that begin development within a short period after being deposited and do not go through diapause. At the other extreme, some eggs do not hatch for almost two years after being laid. In the laboratory, the majority of eggs hatch over a 30-day period when treated in a similar manner. A differential hatching rate can be obtained depending on the length and intensity of the cold treatment. The cold treatment is necessary to break the diapause in the majority of eggs. We are not certain of the situation in the field. Scattered observations indicated that when insecticide failures occurred, root damage was noted early in the season.

Rootworm Habits Need More Study

The movement of adults from field to field, their habits, and patterns of migration have not been closely studied. No population marker has been identified in the present population, hence beetle migration has not been studied since the migration of the western corn rootworm. The adult males emerge 3-5 days prior to the females. Mating has been observed shortly after female emergence, and oviposition begins 14 to 21 days later.
Plant attractiveness has been succeeding year. Chemicals perform similar to the older for insecticide evaluation plots the breakthroughs are foreseen in corn fields severely damaged by larvae. Dako

ta conditions. The reason for this

nings or "trap crops" have been used fresh silks and tassels hence late plant­
ing with late-silking plants usually are associated with the availability of rootworm control. Methods of apply­

planting, and combination liquid trol have been investigated, including broadcast application, subsurface application, and combination liquid insecticide, herbicide and fertilizer treatments. None have given better rootworm control than the conven­
tional seven-inch band applied over the covered seed furrow in front of the presswheel. Post-planting application of insecticides has not generally im­
proved rootworm control under South Dakota conditions. The reason for this situation appears to be associated with both timing of the application in relation to rootworm hatch and frequency and amount of rainfall after application of the insecticides.

Causes of Insecticide Field Failures

A number of human-related factors are the first target of determining why insecticides fail:

Figure 1. Western corn rootworm life cycle.

The eggs are found in the soil, however, oviposition has not been observed in the field. Beetle migration and selection of oviposition sites are not understood although observations indicate general adult migration from fields severely damaged by larvae. Plant attractiveness has been associated with the availability of fresh silks and tassels hence late plant­

ings or "trap crops" have been used for insecticide evaluation plots the succeeding year.

A large number of chemicals have been evaluated for rootworm control the past several years. The new chemicals perform similar to the older compounds and no exciting new breakthroughs are foreseen in corn rootworm control. Methods of applying soil insecticides for rootworm control have been investigated, including broadcast application, subsurface placement, and combination liquid insecticide, herbicide and fertilizer treatments. None have given better rootworm control than the conven­
tional seven-inch band applied over the covered seed furrow in front of the presswheel. Post-planting application of insecticides has not generally im­
proved rootworm control under South Dakota conditions. The reason for this situation appears to be associated with both timing of the application in relation to rootworm hatch and frequency and amount of rainfall after application of the insecticides.

Pollination Affected By Adult Beetles

Adult beetles, upon emergence from the soil, prefer to feed on corn silks, but also are attracted by leaves and pollen. When large numbers of beetles are present during the pollination period, the damage to silks often results in poorly filled ears. Fields with late-silking plants usually are most severely affected. When populations of beetles are high during the pollination period, it may be necessary to practice adult control measures to protect the silks.

Figure 2. Western corn root­

worm lar­

vae (top); inac­
pue pupa stage (bot­
tom).

(1) Calibration of the applicators for the recommended rate of insecticide. In South Dakota the rate is 1 lb. A/A based on 40-inch row spacings. (2) Formulation and/or manufacturing problems causing the product to be under-formulated or degraded prior to application. With some com­

pounds, a few instances of poor for­

mulation occur every year. Present laws on container disposal make this situation harder to evaluate.

(3) Abnormal weather conditions can influence activity of insecticides but generally not enough to cause failure of insecticides applied at planting. Wet weather and soil conditions have been more often associated with poor insecticidal performance, however, when the same compounds are used on dryland and irrigated corn, and from the western cornbelt to higher rainfall areas in the eastern states, deviation in local weather pat­
terns seem less important.

Considerable emphasis has been given to these variables as the major cause of poor insecticidal performance, seldom is the transformation heard. Registered compounds are evaluated across the cornbelt under a variety of rainfall and soil conditions. Comparative insecticidal perfor­

mance ratings are generally within the same range and relationship. Weather and soil factors rarely cause the difference between acceptable control and insecticidal failure.

mance ratings are generally within the same range and relationship. Weather and soil factors rarely cause the difference between acceptable control and insecticidal failure.

Pollination Affected By Adult Beetles

Adult beetles, upon emergence from the soil, prefer to feed on corn silks, but also are attracted by leaves and pollen. When large numbers of beetles are present during the pollination period, the damage to silks often results in poorly filled ears. Fields with late-silking plants usually are most severely affected. When populations of beetles are high during the pollination period, it may be necessary to practice adult control measures to protect the silks.

CONTROL MEASURES

Cultural Control of Larval Populations

Control practices that promote good root systems will help reduce yield loss and lodging. Plant as early as feasible. Experience in the root­

worm areas shows that late-planted corn is often more severely damaged than early-planted corn.

Adult beetles disperse from the corn fields as the season progresses and move into adjoining fields where flowering legumes, sorghums, and weeds are present. If high adult populations were present in such fields during August and September of the preceding year, corn planted in these fields may be heavily infested the following year.

South Dakota State University Entomologists recommend insecticide treatments for corn root worm control on first year corn following small grains, flax, and sorghum under cer­

tain conditions. Problems arise some years in first year corn when northern corn rootworm beetle numbers are high. The predominant species in­

volved was the northern corn root­

worm. In addition where corn root­

worm beetle populations are very high, farmers should consider treating corn following soybeans particularly where complete weed control was not achieved.

There is not sufficient data avail­

able on the effect of fall tillage versus spring tillage, disking versus plowing, etc., and their subsequent effects on rootworm infestations. However, any tillage methods which improve the seedbed and promote good root development are recommended.

Scouting of Fields for Rootworm Potential

The numbers of rootworm beetles in a corn field from August to September is a good indicator of future rootworm problems. Corn growers can determine the potential for rootworm damage for the follow­ing year by counting western and northern corn rootworm beetles from mid-July through August in this way:

1. Make three or more counts for western and northern corn rootworm beetles at 7 to 10-day intervals between August 1 and September 7 in fields to be replanted to corn.
2. Examine 10 plants selected at random in each of five areas of the field. Count all of the western and northern corn rootworm beetles on the 50 plants each time.

3. As you approach a plant, move quietly to avoid disturbing the beetles. Count the beetles on the entire plant, including the ear tip, tassel, leaf surface, and behind the leaf axils.

4. Record the number of beetles you find per plant. If the average is more than one beetle per plant for any sampling date, plan to apply rootworm soil insecticide in the coming season. If average populations range from ½ to one beetle per plant, the probability of economic damage the following year is low, and a soil insecticide is probably unnecessary. If populations do not exceed an average of ½ beetle per plant for any sampling date, a soil insecticide will not be needed the following season.

LARVAL CONTROL USING INSECTICIDES

Rotate Corn Rootworm Insecticides

Field observation over the past years on insecticide performance against corn rootworm show that almost all problems of poor rootworm control were encountered in fields where the same insecticide had been used for several years. This evidence indicates that some changes are taking place, either in the insect or in some environmental factors in these fields, which cause poor insecticide performance. By changing insecticides each year, problems of poor performance or insecticide failures may be eliminated. It is recommended that growers never use the same corn rootworm insecticide on the same field two years in a row.

It is recommended that South Dakota growers rotate their corn rootworm chemicals each year using better performing insecticides. Growers should rotate corn rootworm insecticides, switching from a carbamate to an organic phosphate each year (or vice versa). See county agent for latest insecticide recommendations.

Application of Granular Insecticides

Planting time—The insecticides recommended for larval control are suggested for application in the granular form only and are to be applied with a granular applicator. Apply in 4 to 7-inch bands over the rows (not with the seed) at planting time, and incorporate the insecticide into the upper ½ inch of the soil. Make the granule application in front of press wheels, covering disks, or by dragging chains behind the planter. To avoid granule drift off the row when treatments are made during windy weather, provide plastic guards on each side of the banders. Adequate control of corn rootworm will not be obtained if excessive drift of insecticide from the row is allowed during application.

Carefully calibrate the application equipment each year to obtain the correct dosage. Recommended applications are based on 40-inch row spacings; narrower row spacings require a proportionately higher rate. Basically, apply 10 pounds of 10 percent granules per every 13,080 linear feet of row. It is important that the recommended amount of active ingredient be applied in the correct manner and in the proper place when using row treatments. Do not drag treated fields crosswise or diagonally — this will displace the chemicals in the treatment band.

Post planting time—Although SDSU entomologists are not recommending cultivation treatments, some of the recommended insecticides are registered for side-dressing treatments at first or second cultivation. Special attachments for the cultivator can be purchased or constructed for this purpose. Apply treatments at the base of the plants and incorporate into the soil immediately. When post-planting applications are made, incorporate the insecticide by using a rotary hoe or by covering with the cultivator shovels. If the corn is small, applications can be made over the row or as a band on each side of the row. Emergency treatments also have been applied at lay-by time using high clearance machines to place the insecticide at the base of the plants and disk hillers on a cultivator to incorporate the insecticide into the soil.

Rootworms still will be present in treated fields, particularly outside the treatment band, since none of the insecticides will provide 100 percent control. Ineffective control also may be encountered when extremely dry conditions prevailing during late June and early July prevent local dispersion of the insecticide. Control with insecticides also may be reduced in spots where water remains standing in a field for extended periods of time.

Control of Adult Beetles

South Dakota State University does not recommend spraying cornfields each year to reduce corn rootworm adults in an attempt to reduce or eliminate next year's larval infestations for a number of reasons: (1) it is ecologically unsound from the standpoint of killing beneficial insects and thus will trigger the development of other insect problems, (2) it adds insecticidal hazard to our honeybee and honey industry and interferes with the proper pollination of our seed crops by killing pollinators, (3) it may lead to development of resistance in our

Figure 3. Untreated corn field in Moody County totally destroyed by western corn rootworm, late August 1970.
crop-injuring insects to currently used insecticides, and (4) methods for adult corn rootworm surveillance have not been perfected regarding counting techniques and timing of the spray application. Beetle populations must be kept at one beetle per plant or less during the summer and fall.

Where adult beetles are interfering with pollination, begin adult control measures before silks are damaged to the point where less than $\frac{1}{2}$ inch of the silk is protruding from the tip of the ear and while viable pollen is available in the field. Apply insecticides for adult control before 25 percent of the plants in the field are in silk. See local extension agent for latest recommendations for beetle control.

The first rule in working with any of these materials is to read the label until it is understood completely. Second, follow the manufacturer's safety precautions to the letter.

Wear protective equipment when opening containers and filling insecticide hoppers — rubber gloves, long-sleeved shirt or coveralls, goggles, hat, and a proper respirator if working in the wind.

Remove protective clothing as soon as possible after use. If any insecticide is spilled accidentally on clothing or parts of the body, remove clothing and wash any parts of the body that the insecticide may have contacted.

Always stand upwind and away from the insecticide hoppers when filling. Never breathe dust or fumes. Do not haul containers in your automobile since fumes often are inhaled. Store all insecticides or contaminated equipment away from children and pets. Be sure to burn containers immediately after they are emptied. Bury unused or spilled granules.

Never attempt to sift or break-up lumpy, granular insecticides — the personal hazard is too great! If you find lumps or excessive amounts of fine powder in the granular formulation, return the insecticide to your dealer for replacement or refund.

CAUTION: POISON

All insecticides recommended for corn rootworm control are toxic and therefore dangerous when not handled according to directions.
